Description:

This dataset includes census block group level component scores of various indices from the National Centers for Coastal Ocean Science (NCCOS) Community Risk Assessment of Flooding and Heat Hazards in Baltimore, MD. Indices included in this archived dataset include SoVI[®], ecosystem services valuation, structural exposure, population projections, urban heat hazard, and flood hazard. Each component score is aggregated to the block group level geography provided by the U.S. Census Bureau. Additionally, intermediary raster-based datasets on stormwater flooding hazard are provided, as well as spatial data on wetlands and protected areas.

Methods:

This assessment uses a geospatial, indicator-driven approach to integrate data from a variety of sources related to community risk in Baltimore, MD, and the surrounding 5 counties of Baltimore, Harford, Howard, Anne Arundel, and Queen Anne's. The final aggregation geographies for this assessment are the census block group (2020).

An ecosystem services valuation aggregated index was derived from the total ecosystem services valuation layer of the Maryland Department of Natural Resources (Campbell et al., 2017). These include: (a) atmospheric pollution removal, (b) carbon sequestration, (c) groundwater recharge, (d) nitrogen removal, (e) flood prevention and stormwater mitigation, (f) wildlife habitat and biodiversity, and (g) surface water protection. The value is the mean for each block group, in dollars per year. The input raster data were aggregated to block groups using the average value and normalized 0–1.

A structural exposure aggregated index was calculated from the Department of Homeland Security's HIFLD, Maryland's iMap geospatial database, and ESRI's business analyst data (U.S. Department of Homeland Security, 2022; Maryland iMap, 2024; ESRI Business Analyst, 2023). The index includes the following: banks, bay access points, colleges, critical roadways, drinking water infrastructure, electricity

Data Documentation
NCCOS Community Risk Assessment: RA2 MD

production, emergency shelters, farms, fire stations, gas stations and electric vehicle charging, government facilities, grocery stores, hardware stores, hazardous waste facilities, hospitals, places of worship, police stations, public transit lines, schools, shoreline protection, stormwater infrastructure, and wastewater infrastructure. The total structural exposure index score was developed by aggregating each contributing indicator to the block group by using the ArcGIS's Summarize Within tool, yielding a count for each block group of total sites or total meters of infrastructure (for roads and pipes). It was then calculated by min-max normalizing each contributing indicator to a scale of zero to one and adding the values for each block group together. The resulting index yields a range of 0-22 at the block group level. Data were also normalized to 0–1 at the census block group level.

SoVI[®] was derived from Census data and applied to each census block group (Cutter, & Emrich, 2017).

Population projections and densities are for the year 2050 (Baltimore Metropolitan Council, 2024), and were normalized to 0–1 at the census block group level.

Stormwater flooding potential in the Baltimore region was assessed using the FIGUSED methodology (Kazakis et al., 2015), which integrates seven indicators: Flow Accumulation (F), Rainfall Intensity (I), Geology/Hydrologic Soil Groups (G), Land Use (U), Slope (S), Elevation (E), and Distance to Drainage (D). Each indicator was scored from 0 (low risk) to 1 (high risk), and combined into a composite flood risk index. Flow Accumulation was calculated using a 30x30m Digital Elevation Model (DEM) from the U.S. Geological Survey (United States Geological Survey, 2021). The process included sink-filling, flow direction calculation, and accumulation modeling to quantify surface runoff convergence zones. Rainfall Intensity data came from NOAA and the PRISM Climate Group, based on 30-year normals (1991–2020) at 800m resolution (NOAA National Weather Service, 2024; PRISM Climate Group, 2024). This was resampled to 30m to align with the DEM. Geology/Hydrologic Soil Groups were derived from USDA's Web Soil Survey (National Resources Conservation Service Soil Survey Staff, 2023). Survey areas categorized under hydrologic groups A and B (indicating well-drained, or more absorbent soils) were assigned a value of 0, while areas falling into groups C, D, A/D, B/D, or C/D were given a value of 1, indicating a higher flood potential. Land Use classifications come from 1-meter resolution data by the Chesapeake Conservancy, USGS, and the University of Vermont Spatial Analysis Lab (Chesapeake Conservancy et al., 2022). Impervious surfaces and wetlands were assigned higher flood risk scores based on the following categories (Water & Impervious Structures – 10; Tree Canopy Over Impervious – 8; Barren – 6; Low Vegetation – 4; Tree Canopy & Scrub/Shrub – 2; Aberdeen Proving Ground – No Data). These were normalized and rescaled to 30x30m resolution for integration with the remaining contributing factors.

Slope and Elevation were extracted from the DEM. Lower elevations and flatter slopes that are more prone to water pooling were given higher flood risk scores (normalized 0–1). Distance to Drainage was calculated using flowline data from the National Hydrology Dataset (United States Geological Survey, 2020). A drainage density grid was created and normalized, with higher values indicating proximity to surface water networks. All seven layers were integrated within a GIS framework and summed into an additive index ranging from 0 to 7, then normalized 0–1 at the census block group level. Higher index values indicate greater stormwater flood potential.

Sea level rise estimates are derived from NOAA's Office of Coastal Management (NOAA Office for Coastal Management, 2024). These data from NOAA on sea level rise data use local tide gauge data from the Chesapeake Bay to update sea level rise predictions, updating the database and sea level rise layers regularly with new elevation models and sea level rise predictions. Data were aggregated to the block

group using a spatial join to estimate the total area impacted under a 2-foot year 2050 and a 5-foot year 2100 sea level rise scenario. Data were also normalized to 0–1 at the census block group level.

Category 2 and Category 4 storm surge estimates for this study use the Sea, Lake, and Overland Surge from Hurricanes (SLOSH) Model. This dataset is created by the National Weather Service (NWS) and utilized by the National Hurricane Center (NHC) and the Federal Emergency Management Agency (FEMA), among many disaster response agencies (NOAA National Hurricane Center, 2024). The SLOSH model estimates storm surge heights and associated inundation based on historical, hypothetical, and predicted storms, hurricanes, and winds. Storm surge estimates were calculated by spatially joining input raster data to the block group geographies and calculating the mean inundation depth from the SLOSH model. These data were then normalized 0–1 at the census block group level.

An urban heat index was derived using input data from the Landsat 8 program data, in conjunction with land use/land cover data analysis (Trust for Public Land, 2019). This data shows where certain areas of cities are hotter than the average temperature for that same city as a whole. Urban heat is measured on a scale of 1 to 5, with 1 being a relatively mild heat area (slightly above the mean for the city), and 5 being a severe heat area (significantly above the mean for the city). The absolute heat above mean values are classified into 5 classes. The final urban heat index for the study site used a mean value of the predicted urban heat index for census block groups, indicating severity of heat on a scale of 1-5. Mean values were calculated for the census block groups and normalized 0-1.

Wetland Areas data come from the land use land cover dataset created by the Chesapeake Conservancy, the University of Vermont Spatial Analysis Lab, and the US Geological Survey (Chesapeake Conservancy et al., 2022). One-meter Resolution Land Cover data classified as wetlands were aggregated to the census block group by totaling the percent covered by wetland areas, including riverine, tidal, and terrine wetland extent; these data were also normalized 0–1 at the census block group level.

Protected Areas data are derived from Protected Areas Database of the United States (United States Geological Survey, 2024). The percentage of census block groups covered by protected areas, defined here as public land and voluntarily provided private protected areas from the Protected Areas Database of the United States was calculated, and normalized 0–1 at the census block group level.

Final data were aggregated at the census block group level and visualized using a bivariate choropleth mapping technique. All input data were normalized to a 0–1 scale to allow for direct comparison between indices. Each variable was classified into three categories, low, medium, and high using statistical quantile breaks, which ensure an equal number of observations per class. This classification method supports effective bivariate mapping by enabling the simultaneous visualization of two variables and their relative spatial distribution. As a result, the bivariate classifications reflect relative rankings across both indices, highlighting co-occurring patterns at the block group level.
